Fine-needle aspiration cytology of pituitary adenomas: analysis of 18 cases. To evaluate the cytologic features of pituitary adenomas, fine-needle aspiration (FNA) smears from 18 cases of pituitary adenoma were retrospectively reviewed. The patients included in the study were 13 females and 5 males, with a mean age of 40 years (range: 22-67 years). Seven cases were diagnosed by FNA as normal, and 11 as adenoma of the pituitary. All the lesions were confirmed by surgery, and the cytologic diagnoses were confirmed by histologic examination of the surgical specimens. There were 10 cases of prolactinomas, 2 cases of Cushing's disease, 3 cases of acromegaly, 1 case of hyperprolactinemia, and 1 case of an undifferentiated adenoma. In addition to the typical features of adenomas, a mild degree of pleomorphism was also found in 4 cases. Other common cytologic findings were a lack of pigment in 3 cases, focal atypical cytoplasm in 2 cases, and the presence of unusual nuclei in 1 case. These varied cytologic features may be useful in the diagnosis of pituitary adenomas.

A pharmaceutical or chemical compound for the prevention or treatment of cancer is ordinarily tested for its effect on the growth of tumor cells in culture or on animal models in order to establish its therapeutic potential. Therapeutic potential is not sufficient to warrant the investment of the time and energy to bring a compound to the level of clinical usefulness. The compound must be shown to be active in man, that is, to be able to prevent the growth of human tumors in laboratory animals. In the early stages of such research, animal tumor models are used to determine whether the compound exerts its anticancer effect by interfering with the cellular functions of the cancer cells or by the production of toxic products that kill the cancer cells. One of the most widely used animal tumor models is the transplantable tumor model. It involves the introduction of small amounts of a test compound or a test compound 82157476af
